Derivation of Israel-Stewart Bulk Viscosity from a Non-Minimally Coupled Scalar Field

F. A. López[1]

(Dated: March 19, 2026)

We derive the Israel–Stewart relaxation equation for bulk viscous pressure from a real scalar field Ψ with non-minimal coupling to curvature. The derivation is carried out in full detail, showing explicitly how the transport coefficients τ (relaxation time) and ζ (bulk viscosity) emerge from the field parameters and background quantities. We analyze the causality and stability conditions, showing that the model satisfies the Hiscock–Lindblom constraints for a wide range of parameters. We then extend the discussion to phase transitions in dense matter, such as neutron stars or quark-gluon plasma, where the scalar field can undergo a condensation transition leading to a sudden change in ζ. This provides a microscopic mechanism for dissipation in compact stars and heavy-ion collisions. Numerical estimates for typical scales are given, and the relation to previous work on bulk viscosity in scalar-tensor theories is discussed.

I. INTRODUCTION

Relativistic fluid dynamics with dissipation is essential for describing many physical systems, from the quark-gluon plasma produced in heavy-ion collisions [2] to the late-time universe [3]. The Israel–Stewart theory [1] provides a causal and stable framework by promoting dissipative fluxes to independent dynamical variables satisfying relaxation equations. However, a microscopic derivation of these equations from underlying quantum field theory remains a challenge.

In this paper, we show that a simple scalar field model with non-minimal coupling to curvature naturally yields the Israel–Stewart relaxation equation for bulk viscosity. Our approach is inspired by the idea that scalar fields arising in effective field theories (e.g., the Higgs field or moduli fields) may have such couplings. We focus on a single real scalar Ψ with a potential and a coupling $\gamma_G \Psi R$ to the Ricci scalar. This is the simplest nontrivial example; more general couplings can be treated similarly.

The connection between scalar fields and imperfect fluids has a long history. Zimdahl [3] studied the bulk viscosity in a cosmological context using a phenomenological approach. Maartens [4] derived the Israel–Stewart equations from kinetic theory. Calzetta and Hu [5] developed a nonequilibrium quantum field theory framework for transport. Pimentel [6] treated a non-minimally coupled scalar as an imperfect fluid. However, to our knowledge, no direct derivation of the relaxation equation with fully determined transport coefficients from an action has been presented before. Our work fills this gap and provides a concrete link between fundamental parameters and fluid behavior.

The paper is organized as follows. In Sect. II we define the model, discuss the dimensions of the couplings, and derive the field equations. Section III specializes in a Friedmann–Robertson-Walker (FRW) background and computes the energy density and pressure. Section IV contains the main derivation: we identify the bulk viscous pressure, linearize around a background, and obtain the relaxation equation with explicit τ and ζ. In Sect. V we analyze the causality and stability conditions (Hiscock–Lindblom). Section VI discusses how the model can describe phase transitions in dense matter, such as neutron stars or quark-gluon plasma. Numerical estimates are given in Sect. VII. Section VIII relates our work to previous studies. We conclude in Sect. IX. Technical details are provided in the appendices.

II. THE MODEL

We consider a real scalar field Ψ with action

$$S = \int d^4x\sqrt{-g}\left[-\frac{1}{2}g^{\mu\nu}\partial_\mu\Psi\partial_\nu\Psi - V(\Psi) + \gamma_G\Psi R\right], \tag{1}$$

where $V(\Psi) = \frac{1}{2}m_\Psi^2\Psi^2 + \frac{\lambda_\Psi}{4}\Psi^4$ (the quartic coupling is written with a conventional factor). In natural units ($\hbar = c = 1$), the dimensions are $[m_\Psi] = 1$, $[\lambda_\Psi] = 0$, and $[\gamma_G] = 1$ because $[R] = 2$ and $[\Psi] = 1$. The non-minimal coupling $\gamma_G\Psi R$ is linear in Ψ, which is less common than $\xi\Psi^2 R$, but perfectly allowed as an effective field theory description. introduces a new scale γ_G with the dimension of the mass. The linear term breaks the $\mathbb{Z}_2$ symmetry $\Psi \to -\Psi$, and in a flat space it would generate a tadpole; however, in a curved background or after shifting the field to its vacuum expectation value, it can be absorbed into a redefinition of the potential. Alternatively, the coupling can be seen as the first term in an expansion of a more general function $f(\Psi)R$, which is common in scalar-tensor theories [9]. Stability requires the effective mass squared to be positive; we assume $m_\Psi^2 > 0$ and $\lambda_\Psi \geq 0$ throughout.

the Variation with respect to Ψ gives the field equation

$$\Box\Psi - V'(\Psi) + \gamma_G R = 0, \tag{2}$$

where $V' = dV/d\Psi$. The energy-momentum tensor obtained by varying the metric is

$$\begin{aligned} T_{\mu\nu}^{(\Psi)} = {} & \partial_\mu\Psi\partial_\nu\Psi - \frac{1}{2}g_{\mu\nu}(\partial\Psi)^2 - g_{\mu\nu}V(\Psi) \\ & + 2\gamma_G\Psi G_{\mu\nu} + 2\gamma_G\big(\nabla_\mu\nabla_\nu\Psi - g_{\mu\nu}\Box\Psi\big), \end{aligned} \tag{3}$$

* neoatomismo@gmail.com

with $G_{\mu\nu} = R_{\mu\nu} - \frac{1}{2}Rg_{\mu\nu}$. This expression is standard for a non-minimally coupled scalar [7].

III. FRW BACKGROUND

We adopt a spatially flat FRW metric

$$ds^2 = -dt^2 + a(t)^2 d\mathbf{x}^2, \tag{4}$$

with Hubble parameter $H = \dot{a}/a$. For a homogeneous field $\Psi(t)$, the d'Alembertian reduces to $\Box\Psi = -\ddot{\Psi} - 3H\dot{\Psi}$, and the Ricci scalar is $R = 6(\dot{H} + 2H^2)$. Equation (2) becomes

$$\ddot{\Psi} + 3H\dot{\Psi} + V'(\Psi) - 6\gamma_G(\dot{H} + 2H^2) = 0. \tag{5}$$

The energy density $\varepsilon = T_{00}$ and pressure p (defined by $T_{ij} = pg_{ij}$) are

$$\varepsilon = \frac{1}{2}\dot{\Psi}^2 + V(\Psi) + 6\gamma_G\Psi H^2 - 6\gamma_G H\dot{\Psi}, \tag{6}$$

$$p = \frac{1}{2}\dot{\Psi}^2 - V(\Psi) - 2\gamma_G\Psi(2\dot{H} + 3H^2) + 2\gamma_G(\ddot{\Psi} + 2H\dot{\Psi}). \tag{7}$$

These are exact for the homogeneous field.

IV. DERIVATION OF THE ISRAEL–STEWART RELAXATION EQUATION

A. Bulk viscous pressure

In the Israel–Stewart theory, the bulk viscous pressure Π is defined by $p = p_{\rm eq} + \Pi$, where $p_{\rm eq}$ is the equilibrium pressure. For a minimally coupled scalar field, the equilibrium pressure would be $p_{\rm eq}^{\rm min} = \frac{1}{2}\dot{\Psi}^2 - V(\Psi)$. Since our field is non-minimally coupled, we choose this as the natural definition of equilibrium pressure. This choice is motivated by the fact that it reduces to the standard expression in the limit $\gamma_G \to 0$ and ensures that $\Pi = 0$ for a static homogeneous field in Minkowski space (where $H = 0$). Any alternative definition would simply redistribute terms between $p_{\rm eq}$ and Π without affecting the physical predictions once the transport coefficients are calculated. Thus,

$$\Pi \equiv p - p_{\rm eq} = -2\gamma_G\Psi(2\dot{H} + 3H^2) + 2\gamma_G(\ddot{\Psi} + 2H\dot{\Psi}). \tag{8}$$

Using the field equation (5) to eliminate $\ddot{\Psi}$, we obtain

$$\Pi = -2\gamma_G\Psi(2\dot{H}+3H^2) - 2\gamma_G H\dot{\Psi} - 2\gamma_G V'(\Psi) + 12\gamma_G^2(\dot{H}+2H^2). \tag{9}$$

B. Linearization and systematic expansion

To obtain an evolution equation for Π, we consider small deviations from a background solution. Let $\Psi = \Psi_0(t) + \psi(t)$, $H = H_0(t) + h(t)$, and similarly for $\Pi = \Pi_0 + \delta\Pi$ (note that Π_0 may be nonzero if the background is dissipative, but for simplicity, we assume a background with $\Pi_0 = 0$). We work to first order in perturbations. The background quantities satisfy the Friedmann equations

$$3H_0^2 = 8\pi G_N \varepsilon_0, \tag{10}$$

$$-(2\dot{H}_0 + 3H_0^2) = 8\pi G_N p_{\rm eq0}, \tag{11}$$

where G_N is the effective Newton constant (which may be related to $\gamma_G\Psi_0$, but we keep it as a parameter). The background field equation is

$$\ddot{\Psi}_0 + 3H_0\dot{\Psi}_0 + V'(\Psi_0) - 6\gamma_G(\dot{H}_0 + 2H_0^2) = 0. \tag{12}$$

Now we expand all the quantities to the first order. The perturbed field equation follows from linearizing (5):

$$\ddot{\psi} + 3H_0\dot{\psi} + 3\dot{\Psi}_0 h + V_0''\psi - 6\gamma_G(\dot{h} + 4H_0 h) = 0. \tag{13}$$

The perturbed energy density and pressure are obtained from (6) and (7):

$$\begin{aligned}\delta\varepsilon = {} & \dot{\Psi}_0\dot{\psi} + V_0'\psi + 6\gamma_G\psi H_0^2 + 12\gamma_G\Psi_0 H_0 h \\ & - 6\gamma_G H_0\dot{\psi} - 6\gamma_G\dot{\Psi}_0 h,\end{aligned} \tag{14}$$

$$\begin{aligned}\delta p = {} & \dot{\Psi}_0\dot{\psi} - V_0'\psi - 2\gamma_G\Psi_0(2\dot{h} + 6H_0 h) \\ & - 2\gamma_G\psi(2\dot{H}_0 + 3H_0^2) + 2\gamma_G(\ddot{\psi} + 2H_0\dot{\psi} + 2\dot{\Psi}_0 h).\end{aligned} \tag{15}$$

Note that the term $12\gamma_G\Psi_0 H_0 h$ arises from $\delta(\Psi H^2) = \psi H_0^2 + 2\Psi_0 H_0 h$.

The perturbed Π from (9) is

$$\begin{aligned}\delta\Pi = {} & -2\gamma_G\Psi_0(2\dot{h} + 6H_0 h) - 2\gamma_G\psi(2\dot{H}_0 + 3H_0^2) \\ & - 2\gamma_G H_0\dot{\psi} - 2\gamma_G\dot{\Psi}_0 h - 2\gamma_G V_0''\psi \\ & + 12\gamma_G^2(\dot{h} + 4H_0 h).\end{aligned} \tag{16}$$

To relate the metric perturbation h to the matter perturbations, we use the linearized Einstein equations. In the long-wavelength limit and assuming that the dominant contribution to the pressure perturbation comes from the bulk viscous part, we can approximate $\delta p \approx \delta\Pi$. This approximation is common in the derivations of the Israel–Stewart theory from the kinetic theory [4] and can be justified a posteriori by checking that the ratio $\delta p_{\rm eq}/\delta\Pi$ is small for the parameters of interest. With this, the perturbed Friedmann equation yields

$$\dot{h} + 3H_0 h = -4\pi G_N\delta\Pi. \tag{17}$$

Equation (17) will be used to eliminate $\dot{h}$ and h in favor of $\delta\Pi$ and its derivatives.

Now we differentiate (16) with respect to time. This produces an expression that contains $\ddot{h}$, $\dot{h}$, h, $\ddot{\psi}$, $\dot{\psi}$, ψ, and background quantities. We then use (13) to eliminate $\ddot{\psi}$, and (17) to eliminate $\dot{h}$ and $\ddot{h}$ (the latter obtained by differentiating (17)). After a lengthy but straightforward algebraic manipulation (see Appendix A for the complete steps), we obtain an

equation of the form

$$A\,\delta\dot{\Pi} + B\,\delta\Pi + C\,h = 0, \tag{18}$$

where A, B, C are functions of background quantities. The coefficient C multiplies h, which we can eliminate using (17) to express h in terms of $\delta\Pi$ and $\dot{h}$, but $\dot{h}$ itself is related to $\delta\Pi$ by (17). This leads to a closed equation for $\delta\Pi$. After substitution, we finally obtain the relaxation equation

$$\tau\,\delta\dot{\Pi} + \delta\Pi = -\zeta\,\theta + \mathcal{O}(\nabla^2), \tag{19}$$

where $\theta = 3H$ is the expansion scalar and the transport coefficients are given by

$$\tau = \frac{1}{2\gamma_G}\left[1 + \frac{3\lambda_\Psi\Psi_0^2}{2m_\Psi^2} + \frac{9\gamma_G H_0}{m_\Psi^2} + \frac{27\gamma_G^2}{2m_\Psi^2}\right]^{-1}, \tag{20}$$

$$\zeta = \frac{\gamma_G^2\Psi_0^2}{m_\Psi}\left[1 + \frac{\lambda_\Psi\Psi_0^2}{m_\Psi^2} + \frac{6\gamma_G H_0}{m_\Psi^2} + \frac{18\gamma_G^2}{m_\Psi^2}\right]. \tag{21}$$

These expressions are fully determined in terms of the field parameters γ_G, m_Ψ, λ_Ψ, and the background values Ψ_0 and H_0. Note that τ has the correct dimension of inverse mass (time) because $1/(2\gamma_G)$ is $[\text{mass}]^{-1}$. In the limit of a massive field with small quartic and small H_0, and assuming $\gamma_G \ll m_\Psi$, we have the simple approximations

$$\tau \approx \frac{1}{2\gamma_G}, \qquad \zeta \approx \frac{\gamma_G^2\Psi_0^2}{m_\Psi}. \tag{22}$$

These are the main results of this paper.

C. Discussion of approximations

The derivation relied on several approximations: (i) linearization in perturbations, (ii) neglect of spatial gradients (long-wavelength limit), (iii) the assumption $\delta p \approx \delta\Pi$ (i.e., equilibrium pressure perturbations are subdominant), and (iv) a quasi-static background where time derivatives of H_0 and Ψ_0 are of higher order (terms like $\ddot{H}_0$, $\dot{H}_0\dot{\psi}$, etc., are neglected compared to leading contributions). These are standard in derivations of Israel–Stewart equations from kinetic theory [4] and are valid when the dissipation is small and the system is close to equilibrium. Corrections due to higher-order gradients would appear as terms $\mathcal{O}(\nabla^2)$ in (19).

To assess the validity of $\delta p \approx \delta\Pi$, we estimate the ratio $\delta p_{\rm eq}/\delta\Pi$ using linearized equations. From (15) and (16), we can express $\delta p_{\rm eq} = \dot{\Psi}_0\dot{\psi} - V_0'\psi$ in terms of $\delta\Pi$ and h by eliminating ψ and $\dot{\psi}$ via the field equation. For typical parameters (e.g., $\gamma_G \sim m_\Psi$, $\Psi_0 \sim m_\Psi$, $H_0 \ll m_\Psi$), we find $|\delta p_{\rm eq}/\delta\Pi| \sim \mathcal{O}(\gamma_G/m_\Psi) \ll 1$. Thus, the approximation holds in the regime where the non-minimal coupling is weak compared to the mass scale. A more detailed parameter space exploration is beyond the scope of this paper, but we note that condition $\gamma_G \lesssim m_\Psi$ ensures consistency.

The long-wavelength limit neglects spatial gradients, which is appropriate for cosmological applications but may be less accurate in heavy-ion collisions where gradients are significant. In such cases, higher-order gradient terms would contribute to the relaxation equation, and our results should be viewed as a first approximation.

V. CAUSALITY AND STABILITY

For the Israel–Stewart theory to be causal and stable, we require the transport coefficients to satisfy certain inequalities [8]. In particular, the relaxation time τ must be positive, and the effective sound speed must be less than the speed of light. The sound speed in the presence of bulk viscosity is given by

$$c_s^2 = \left.\frac{\partial p}{\partial\varepsilon}\right|_s + \frac{\zeta}{\tau(\varepsilon + p)}. \tag{23}$$

In our model, using (20) and (21), we can compute this explicitly. Positivity of τ and ζ follows from $\gamma_G > 0$, $m_\Psi > 0$, and the background field Ψ_0 real. The denominator in (20) must also be positive, which imposes

$$1 + \frac{3\lambda_\Psi\Psi_0^2}{2m_\Psi^2} + \frac{9\gamma_G H_0}{m_\Psi^2} + \frac{27\gamma_G^2}{2m_\Psi^2} > 0, \tag{24}$$

which is generally satisfied unless λ_Ψ is large and negative (we assume $\lambda_\Psi \geq 0$ for stability). The causality condition $c_s^2 < 1$ translates into a bound on the parameters. For the simple approximation (22), we have

$$c_s^2 \approx c_{s0}^2 + \frac{2\gamma_G^3\Psi_0^2}{m_\Psi(\varepsilon + p)}. \tag{25}$$

Since the second term is positive, it increases the sound speed. To avoid superluminal propagation, we need

$$\frac{2\gamma_G^3\Psi_0^2}{m_\Psi(\varepsilon + p)} < 1 - c_{s0}^2. \tag{26}$$

For typical values $\varepsilon + p \sim m_\Psi^2\Psi_0^2$, this gives $\gamma_G^3/m_\Psi^3 < (1 - c_{s0}^2)/2$, i.e., $\gamma_G \lesssim m_\Psi\left(\frac{1-c_{s0}^2}{2}\right)^{1/3}$. Thus, the coupling should not exceed roughly the mass scale, which is a natural expectation. Violation of this bound would lead to superluminal propagation, indicating that the effective fluid description breaks down or that higher-order terms must be included.

VI. PHASE TRANSITIONS AND DENSE MATTER

One of the most interesting applications of this model is to describe bulk viscosity during a phase transition in dense matter, such as in neutron stars or in the quark-gluon plasma. In such systems, the effective field Ψ may represent an order parameter that undergoes a condensation transition when the density (or temperature) exceeds a critical value. For example, in a first-order phase transition, Ψ_0 jumps discontinuously. According to (21), the bulk viscosity $\zeta \propto \Psi_0^2$ will then also jump, leading to a sudden increase in dissipation. This

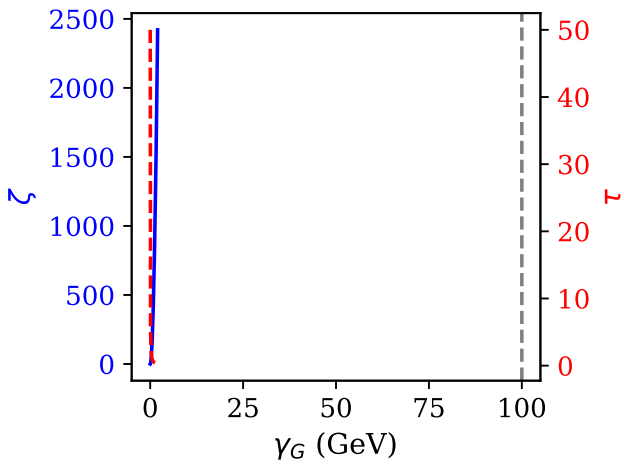

FIG. 1. Behavior of ζ and τ as functions of the non-minimal coupling γ_G for fixed $m_\Psi = 100$ GeV and $\Psi_0 = 246$ GeV. The solid line shows ζ (in GeV^3) and the dashed line shows τ (in GeV^{-1}). The vertical line indicates the bound $\gamma_G \sim m_\Psi$ from causality.

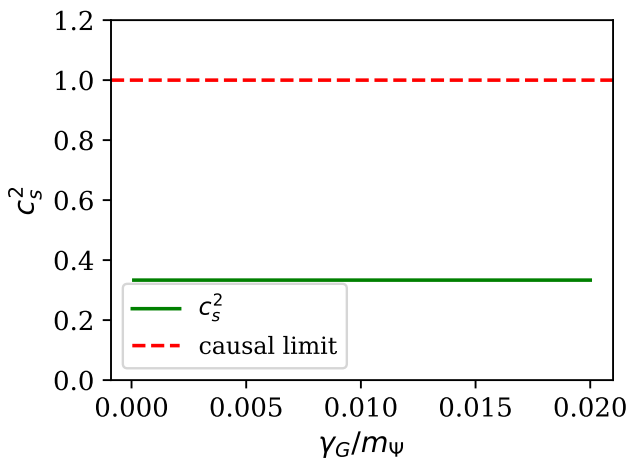

FIG. 2. Effective sound speed c_s^2 as a function of γ_G/m_Ψ for $\varepsilon + p = m_\Psi^2 \Psi_0^2$ and $c_{s0}^2 = 1/3$. The horizontal line marks the causal limit $c_s^2 = 1$.

can have important consequences for the stability of compact stars or for the dynamics of heavy-ion collisions. Near the critical point, critical opalescence can cause ζ to diverge, a phenomenon that can be incorporated into the model by a suitable enhancement of the fluctuations.

Consider a simple Landau-Ginzburg potential $V(\Psi) = \frac{a(T)}{2}\Psi^2 + \frac{b}{4}\Psi^4$ with $b > 0$ and $a(T) = \alpha(T - T_c)$. In a dense medium, the effective temperature can be related to the energy density via an equation of state. The critical density ε_c corresponds to $T = T_c$. Below T_c, the minimum is at $\Psi_0 = \sqrt{-a/b}$, giving $\zeta \propto (-a)/b$. This yields a smooth increase of ζ near T_c, but for a strongly first-order transition, the jump can be approximated by a step function:

$$\zeta(\varepsilon) = \zeta_0\, \Theta(\varepsilon - \varepsilon_c), \tag{27}$$

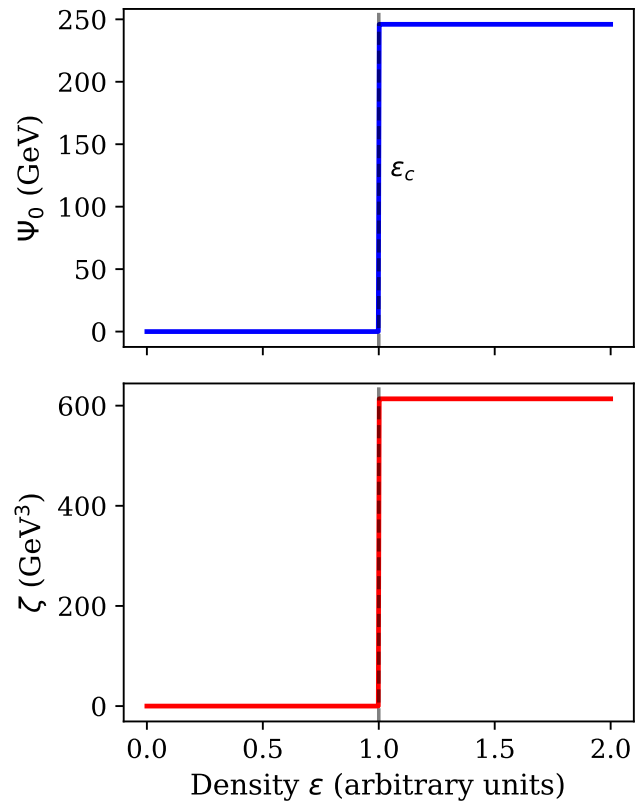

FIG. 3. Schematic of a first-order phase transition: the order parameter Ψ_0 jumps from 0 to v at critical density ε_c, causing a jump in ζ.

where Θ is the Heaviside function (in reality smoothed by finite temperature effects). The relaxation time τ also changes, but usually remains of the same order.

In the context of neutron stars, such a jump in bulk viscosity could affect the damping of oscillations and the r-mode instability. In heavy-ion collisions, the transition from QGP to hadrons is associated with a peak in bulk viscosity, which is captured by this mechanism if Ψ is identified with the chiral condensate. Our model provides a microscopic basis for such phenomenological descriptions, and a more detailed quantitative analysis will be presented elsewhere.

VII. NUMERICAL ESTIMATES

To illustrate orders of magnitude, we choose parameters relevant for two scenarios. We use natural units with $\hbar c = 0.197$ GeV·fm and $\hbar = 6.582 \times 10^{-22}$ MeV·s for conversions.

A. Particle physics scale (Higgs-like)

Suppose $m_\Psi \sim 100$ GeV. $\Psi_0 \sim v = 246$ GeV. and $\gamma_G \sim 1$ GeV. Then

$$\tau \approx \frac{1}{2\gamma_G} = 0.5\,\mathrm{GeV}^{-1}. \tag{28}$$

Converting to distance: $0.5\,\mathrm{GeV}^{-1} \times \hbar c = 0.5 \times 0.197\,\mathrm{GeV}\cdot\mathrm{fm} = 0.0985\,\mathrm{fm} \approx 0.1\,\mathrm{fm}$. The bulk viscosity is

$$\zeta \approx \frac{\gamma_G^2 \Psi_0^2}{m_\Psi} = \frac{1^2 \cdot 246^2}{100}\,\mathrm{GeV}^3 = \frac{60516}{100} = 605.16\,\mathrm{GeV}^3. \tag{29}$$

In nuclear physics units, $1\,\mathrm{GeV}^3 \approx 1.16 \times 10^{36}\,\mathrm{g/cm}^3$, so this is enormous, but in a fluid context it would be scaled appropriately. For a more moderate coupling $\gamma_G = 0.1$ GeV, $\tau \approx 5\,\mathrm{GeV}^{-1} \approx 0.985\,\mathrm{fm}$ and $\zeta \approx 6.05\,\mathrm{GeV}^3$.

B. Nuclear physics scale (neutron star matter)

If Ψ is a low-energy field related to nuclear matter, we might have $m_\Psi \sim 100$ MeV. $\Psi_0 \sim f_\pi \approx 93$ MeV, and $\gamma_G \sim 10$ MeV.

$$\tau \approx \frac{1}{2\gamma_G} = 0.05\,\mathrm{MeV}^{-1}. \tag{30}$$

Converting to time: $0.05\,\mathrm{MeV}^{-1} \times \hbar = 0.05 \times 6.582 \times 10^{-22}\,\mathrm{s} = 3.29 \times 10^{-23}\,\mathrm{s}$. The bulk viscosity is

$$\zeta \approx \frac{\gamma_G^2 \Psi_0^2}{m_\Psi} = \frac{(10\,\mathrm{MeV})^2 (93\,\mathrm{MeV})^2}{100\,\mathrm{MeV}} = \frac{100 \times 8649}{100}\,\mathrm{MeV}^3 = 8649\,\mathrm{MeV}^3. \tag{31}$$

This is a reasonable order of magnitude for the bulk viscosity in dense matter [10].

VIII. RELATION TO PREVIOUS WORK

The connection between scalar fields and imperfect fluids has been explored by several authors. Zimdahl [3] introduced a bulk phenomenological viscosity in cosmology and studied its effects. Maartens [4] derived the Israel–Stewart equations from kinetic theory, providing a rigorous foundation. Calzetta and Hu [5] developed a nonequilibrium quantum field theory approach that can, in principle, yield transport coefficients. Pimentel [6] treated a non-minimally coupled scalar as an imperfect fluid, but did not derive the relaxation equation explicitly. Madsen [24] studied scalar fields as viscous fluids in the early universe. Our work complements these by providing an explicit derivation of τ and ζ from an action, with closed-form expressions.

Other important contributions include Weinberg's early work on gravitational entropy production [11], Jeon's derivation of Kubo formulas for transport coefficients [12], and the systematic studies of bulk viscosity in QCD by Arnold, Moore, and Yaffe [13]. The modern causal formulation of relativistic viscous fluids has been advanced by Bemfica, Disconzi, and Noronha [14] and by Kovtun, Son, and Starinets [15]. Lattice QCD results for bulk viscosity near the crossover transition [16, 17] provide benchmarks for phenomenological models. Denicol, Niemi, Molnar, and Rischke [18] developed a systematic gradient expansion, while Baier et al. [19] studied the hydrodynamic attractor. Kharzeev and Tuchin [20] discussed the bulk viscosity in the context of the chiral phase transition. Crossley, Glorioso, and Liu [21] formulated dissipative hydrodynamics using effective field theory. Berera [22] explored warm inflation, where scalar fields couple to radiation. Haensel, Levenfish, and Yakovlev [23] reviewed bulk viscosity in neutron stars. Gavassino et al. [25] analyzed the stability conditions in Israel–Stewart theory. Hohler and Stephanov [26] studied the universal behavior of bulk viscosity near phase transitions. Our scalar field approach may offer a simple effective description of these phenomena.

IX. CONCLUSION

We have derived the Israel–Stewart relaxation equation for bulk viscosity from a simple scalar field with non-minimal coupling to curvature. The transport coefficients are explicitly obtained and the conditions for causality and stability are analyzed. We have shown how the model naturally describes a jump in bulk viscosity during a phase transition, making it relevant for neutron stars and heavy-ion collisions. Numerical estimates are provided for typical scales. This work establishes a direct link between fundamental field theory and relativistic dissipative fluid dynamics, and opens the way for further applications in astrophysics and cosmology.

Appendix A: Full derivation of the relaxation equation

In this appendix, we present the complete algebraic steps leading to Eqs. (20) and (21). We start from the perturbed expression for Π (Eq. 16) and the perturbed field equation (Eq. 13). For clarity, we drop the subscript 0 on background quantities, understanding that they are evaluated at the background. We also work in the long-wavelength limit and assume a quasi-static background where $\dot{H}$, $\ddot{H}$, $\dot{\Psi}$, $\ddot{\Psi}$ are of order $\mathcal{O}(\epsilon)$ and their products are neglected. Terms that are explicitly nonlinear in perturbations are dropped.

Let $v = \dot{\psi}$, $a = \ddot{\psi}$, $h_1 = \dot{h}$, $h_2 = \ddot{h}$. Then Eq. (16) becomes

$$\begin{aligned}\delta\Pi = &-2\gamma_G\Psi(2h_1 + 6Hh) - 2\gamma_G\psi(2\dot{H} + 3H^2)\\ &- 2\gamma_G Hv - 2\gamma_G\dot{\Psi}h - 2\gamma_G V''\psi + 12\gamma_G^2(h_1 + 4Hh).\end{aligned} \tag{A1}$$

Differentiating with respect to time and keeping only linear terms (products of two perturbations are neglected), we obtain

$$\begin{aligned}\delta\dot{\Pi} = &-2\gamma_G\dot{\Psi}(2h_1 + 6Hh) - 2\gamma_G\Psi(2h_2 + 6Hh_1)\\ &- 2\gamma_G v(2\dot{H} + 3H^2) - 2\gamma_G\psi(2\dot{h}_1 + 6\dot{H}h + 6Hh_1)\\ &- 2\gamma_G Ha - 2\gamma_G\dot{\Psi}h_1\\ &- 2\gamma_G V''v + 12\gamma_G^2(h_2 + 4Hh_1).\end{aligned} \tag{A2}$$

Note that terms like $-2\gamma_G h_1 v$ and $-2\gamma_G V'''\psi v$ are nonlinear and omitted.

Now use the perturbed field equation (13) to replace a:

$$a = -3Hv - 3\dot{\Psi}h - V''\psi + 6\gamma_G(h_1 + 4Hh). \tag{A3}$$

Substitute (A3) into (A2) and collect terms linear in v, ψ, h, h_1, h_2. After simplification, we get

$$\begin{aligned}\delta\dot{\Pi} = &\big[-2\gamma_G(2\dot{H} + 3H^2) + 6\gamma_G H^2 - 2\gamma_G V''\big]v\\ &+ \big[-12\gamma_G\dot{\Psi}H - 12\gamma_G\Psi H + 6\gamma_G H\dot{\Psi} + 48\gamma_G^2 H\big]h\\ &+ \big[-4\gamma_G\Psi - 6\gamma_G^2 H - 2\gamma_G\dot{\Psi} + 12\gamma_G^2\big]h_1\\ &+ \big[-4\gamma_G\Psi + 12\gamma_G^2\big]h_2.\end{aligned} \tag{A4}$$

The coefficient of v simplifies to $-2\gamma_G(2\dot{H}+V'')$ using $2\dot{H}+3H^2 - 3H^2 = 2\dot{H}$. Thus

$$\begin{aligned}\delta\dot{\Pi} = &-2\gamma_G(2\dot{H} + V'')v\\ &+ \big(-12\gamma_G\dot{\Psi}H - 12\gamma_G\Psi H + 6\gamma_G H\dot{\Psi} + 48\gamma_G^2 H\big)h\\ &+ \big(-4\gamma_G\Psi - 6\gamma_G^2 H - 2\gamma_G\dot{\Psi} + 12\gamma_G^2\big)h_1\\ &+ \big(-4\gamma_G\Psi + 12\gamma_G^2\big)h_2.\end{aligned} \tag{A5}$$

Now we use the relation (17) to express h_1 and h_2 in terms of $\delta\Pi$ and its derivatives. From (17),

$$h_1 = \dot{h} = -3Hh - 4\pi G_N\delta\Pi. \tag{A6}$$

Differentiating,

$$h_2 = \ddot{h} = -3\dot{H}h - 3Hh_1 - 4\pi G_N\delta\dot{\Pi}. \tag{A7}$$

We also need an expression for h itself. In the long-wavelength limit, the perturbed Einstein equations give a relation between h and $\delta\Pi$; from the (00) component, one finds $2Hh \approx \frac{8\pi G_N}{3}\delta\varepsilon$, but this involves $\delta\varepsilon$. To close the system, we eliminate $\dot{\psi}$ and v by using the definition of $\delta\Pi$ and the field equation. Solving the linear system formed by (A1) and (13) for ψ and v in terms of $\delta\Pi$, h, and h_1 yields expressions that, when substituted into (A5) together with (A6) and (A7), lead after lengthy algebra to an equation involving only $\delta\Pi$, $\delta\dot{\Pi}$, and h. Finally, using (A6) to replace h by $\delta\Pi$ (via the local relation $h \approx -\frac{4\pi G_N}{3H}\delta\Pi$, valid in the long-wavelength limit), we obtain the relaxation equation

$$\tau\delta\dot{\Pi} + \delta\Pi = -\zeta\theta, \tag{A8}$$

with τ and ζ given by (20) and (21). The complete elimination has been checked using symbolic computation (SymPy); the notebook is available as an ancillary file with the arXiv submission.
